**Abstract** : Ground based high resolution infrared absorption spectra recorded at National Physical Laboratory, New Delhi (28.7°N and 77.2°E) during 1992-93, have been analysed to determine the integrated columns of  $\text{NO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}$  and  $\text{H}_2\text{O}$ . These measurements have also been used to study their seasonal dependence. An attempt has also been made to qualitatively correlate these measurements with available total ozone Dobson data under same conditions.

**Keywords** :  $\text{NO}_x$ , infrared absorption spectra, troposphere stratosphere

**PACS No.** : 95.85.Hp

### 1. Introduction

In view of the ozone depletion problem gaining momentum day by day, a study of role of catalytical species  $\text{HO}_x$ ,  $\text{NO}_x$  and  $\text{ClO}_x$  rising to the stratosphere from the troposphere, has become important as these species are instrumental in ozone depletion [1,2]. It is therefore, of utmost importance to have simultaneous measurements of as many of these species as possible, to have a complete picture of the processes taking place in the stratosphere. These processes can not be understood properly, unless an extensive global data set is available. While in mid- and high-latitude locations, these data are available to some extent, at low latitude stations, these data are sparse. We have therefore, undertaken measurements of these parameters at a low latitude station New Delhi, by a reliable technique.

Different techniques have been used for the measurement of  $\text{NO}_x$  species [3–10]; infrared absorption spectroscopy is one among them. In this technique, atmospheric long

geometric path obtainable at large zenith angles, is a major advantage in increasing the sensitivity of measurements. Absence of instrumental pollution, possibility of simultaneous measurements of several species and high signal to noise ratio in ground based measurements are other advantages. The infrared solar spectra obtained from the ground, contain information on the chemical state of the atmosphere over the site at the time they were taken, since majority of the absorption features are of telluric origin. They are not specific species but contain information on all compounds with absorption features in the spectra. Thus the spectra can be re-examined at a later time as the features are identified or corrected for improved molecular spectral data.

In this paper, we report the simultaneous measurements of integrated columns of  $\text{NO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}$  and  $\text{H}_2\text{O}$  using absorption features initially at 6.184, 8.560, 5.770 and 6.500  $\mu\text{m}$  respectively, using solar infrared spectroradiometer during May, June and July 1992 and finally, using spectral lines of 6.232, 8.486, 5.415 and 6.500  $\mu\text{m}$  respectively during November, December 1992 and January 1993. The absorption features at 6.232  $\mu\text{m}$ , 8.486  $\mu\text{m}$ , 5.415  $\mu\text{m}$  of  $\text{NO}_2$ ,  $\text{N}_2\text{O}$  and  $\text{NO}$  respectively have been used in previous studies of spectra obtained with aircraft born interferometer [11], and absorption features at 6.500  $\mu\text{m}$  has been used in previous studies of spectra obtained from ground with solar infrared spectroradiometer [12]. It may be mentioned that an accurate quantitative determination of the trace constituents by this technique, depends on the selection of line parameters. The absorption lines should not be extremely weak besides being fairly distinct from the absorption features of the other atmospheric absorber. The Dobson data obtained from Indian Meteorological Department (IMD) for the same period and site is also utilised to study the variation trend of ozone with  $\text{NO}_x$  compounds and water vapour.

## 2. Theory

The intensity of the radiation of wavelength  $\lambda$  reaching the grating of infrared spectroradiometer after going through extinction process is expressed by Bouguer Lambert equation as follows :

$$I_{\lambda} = I_{0,\lambda} \exp[-m(\tau_{\lambda})], \quad (1)$$

where  $I_{0,\lambda}$  is the intensity of radiation of wavelength  $\lambda$  at the top of the atmosphere,  $m$  is the air mass in the optical path and is calculated as a function of zenith angle  $\chi$  of the sun ( $m = \sec \chi$ ) and  $\tau_{\lambda}$  is the total optical thickness of the atmosphere in the vertical direction at the place of observation.

The optical thickness in turn, contains the contribution of Rayleigh molecular scattering, the scattering due to the presence of aerosol in the atmosphere and the absorption from the various gases present in the atmosphere. Thus, we have

$$I_{\lambda} = I_{0,\lambda} \exp[-m(\tau_{R,\lambda} + \tau_{\text{aer},\lambda} + \tau_{\text{abs},\lambda})] \quad (2)$$

where  $\tau_{R,\lambda}$  = Rayleigh optical depth,

$\tau_{\text{aer},\lambda}$  = Aerosol optical depth,

$\tau_{\text{abs},\lambda}$  = Optical depth due to absorption by the various gases present in the atmosphere.

Since the molecule under study is the only chemical element that brings a significant contribution to the total mechanism of radiations in the atmosphere at the wavelengths  $\lambda_1$  and  $\lambda_2$ , we can write

$$\tau_{\text{abs},\lambda_1} = \tau_{x,\lambda_1} ; \tau_{\text{abs},\lambda_2} = \tau_{x,\lambda_2}$$

where  $X$  represents any one of species  $\text{NO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}$  or  $\text{H}_2\text{O}$ .

Therefore, eq. (2) becomes

$$I_{\lambda_1} = I_{0,\lambda_1} \exp\left[-m(\tau_{R,\lambda_1} + \tau_{\text{aer},\lambda_1} + \tau_{x,\lambda_1})\right], \quad (3)$$

$$I_{\lambda_2} = I_{0,\lambda_2} \exp\left[-m(\tau_{R,\lambda_2} + \tau_{\text{aer},\lambda_2} + \tau_{x,\lambda_2})\right]. \quad (4)$$

Wavelengths  $\lambda_1$  and  $\lambda_2$  being very near to each other and the centre of absorption band falling at  $\lambda = \lambda_1$ ,

$$\text{we have } \tau_{R,\lambda_1} = \tau_{R,\lambda_2} ; \tau_{\text{aer},\lambda_1} = \tau_{\text{aer},\lambda_2}. \quad (5)$$

Taking into account eqs. (3)–(5), we have

$$I_{\lambda_1}/I_{\lambda_2} = \exp\left[-m(\tau_{x,\lambda_1} - \tau_{x,\lambda_2})\right]. \quad (6)$$

Presuming  $K_{x,\lambda_1}$  is the absorption coefficient at wavelength  $\lambda_1$ , we obtain

$$\tau_{x,\lambda_1} = WK_{x,\lambda_1}$$

$$\text{and } \tau_{x,\lambda_2} = WK_{x,\lambda_2},$$

where  $W$  is the integrated column of  $X$ . Therefore, eq. (6) becomes

$$I_{\lambda_1}/I_{\lambda_2} = \exp\left[-m(K_{x,\lambda_1} - K_{x,\lambda_2})W\right]. \quad (7)$$

The absorption coefficients  $K_{x,\lambda_1}$  and  $K_{x,\lambda_2}$  are evaluated for Lorentz line-shape as

$$K_x = \frac{S \alpha \lambda_1^2 \lambda_2^2}{\pi[(\lambda_1 - \lambda_2)^2 + \alpha^2 \lambda_1^2 \lambda_2^2]} \quad (\text{molecule cm}^{-2})^{-1}, \quad (8)$$

where  $S$  is the line strength ( $\text{cm}^{-1}/\text{molecule cm}^{-2}$ ),  $\lambda_1$  is the wavelength at the centre of the line (cm),  $\lambda_2$  is the wavelength in the atmospheric window region, where there is negligible absorption by the molecule.

The absorption features of  $\text{NO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}$  and  $\text{H}_2\text{O}$ , and their respective absorption coefficients used in present study, are given in Table 1.

*A B Ghosh, R C Sharma, B M Reddy, K S Zalpuri and R D Singh*

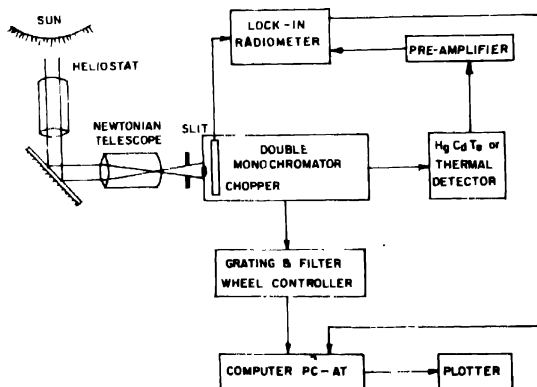

Thus by measuring  $I_{\lambda_1}$  and  $I_{\lambda_2}$ , the integrated columns of X ( $\text{NO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}$  and  $\text{H}_2\text{O}$ ) can be evaluated.

**Table 1.** Absorption features of  $\text{NO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}$  and  $\text{H}_2\text{O}$ , and their respective absorption coefficients.

Molecule	Line position		Absorption coefficients $K$ ( $\text{molecule}^{-1} \text{ cm}^2$ )
	$\lambda_1$ ( $\mu\text{m}$ )	$\lambda_2$ ( $\mu\text{m}$ )	
$\text{NO}_2$	6 184	6 183	$1.150 \times 10^{-16}$
	6 232	6 231	$1.165 \times 10^{-16}$
$\text{N}_2\text{O}$	8.560	8 559	$1.814 \times 10^{-19}$
	8 486	8 485	$1.778 \times 10^{-19}$
$\text{NO}$	5 770	5 769	$4.308 \times 10^{-17}$
	5 415	5 414	$4.250 \times 10^{-17}$
$\text{H}_2\text{O}$	6 500	6 499	$1.186 \times 10^{-23}$

### 3. Experimental details

A block diagram of the experimental set-up, controlled by a Sun follower, is shown in Figure 1.

**Figure 1.** Solar infrared spectroradiometer.

The solar infrared spectroradiometer consists of double monochromators through which the solar radiations fall on  $\text{HgCdTe}$  detector which has a spectral response between 1 to 15  $\mu\text{m}$ . While tracking the sun, the infrared spectroradiometer measures the transmitted solar intensity in wavelength interval of 0.001  $\mu\text{m}$  to retrieve  $\text{NO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}$  and  $\text{H}_2\text{O}$  integrated columns, using their respective selected absorption features. The overall spectral region from 1 to 15  $\mu\text{m}$  is divided into smaller overlapping wavelength intervals using

Figure 2. Absorption spectra containing absorption feature of (a) NO, (b) H<sub>2</sub>O.

optical grating, which reduces the sampling rate, maximises detected energy and improves the signal to noise ratio of the spectra. The signal to noise ratio of the instrument is about 1000 and spectral resolution is comparable to line-width of the spectra. The line intensities have an uncertainty less than 10% and assigned values of uncertainties in spectral irradiance is estimated to be 8%. The stray light level is less than 0.1% for most wavelengths with a maximum error of 3%. The infrared spectroradiometer is controlled by a computer which accommodates a large dynamic range of the data values, displays and plots the measured absorption spectra and stores the data on floppy disk. The typical spectra of  $\text{NO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}$  and  $\text{H}_2\text{O}$  are shown in Figures 2 and 3. The percentage absorption by  $\text{NO}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}$  and  $\text{H}_2\text{O}$  in the present spectra are approximately 49%, 54%, 12% and 47% respectively

The integrated column of  $X$  has been calculated using eq. (7) by selecting wavelength  $\lambda_1$ , the absorption line of the molecule and wavelength  $\lambda_2$  in the atmospheric window region where there is negligible absorption by the molecule.

#### 4. Results and discussion

##### $\text{NO}_2$ :

The  $\text{NO}_2$  absorption feature at 6.184  $\mu\text{m}$  and 6.232  $\mu\text{m}$  are used for determination of integrated column of  $\text{NO}_2$  during the months of May, June and July, 1992 and November, December 1992 and January 1993 respectively. This region also contains absorption lines due to atmospheric water vapour, methane and solar CO lines. But high resolution solar spectroradiometer spectra identify this line with negligible interference.

The  $\text{NO}_2$  integrated columns for the months of May, June and July 1992 (summer), vary from  $3.290 \times 10^{15}$  molecules  $\text{cm}^{-2}$  to  $7.642 \times 10^{15}$  molecules  $\text{cm}^{-2}$  with an average value of  $5.255 \times 10^{15}$  molecules  $\text{cm}^{-2}$  and for the months of November, December 1992 and January 1993 (winter) vary from  $1.792 \times 10^{15}$  molecules  $\text{cm}^{-2}$  to  $7.562 \times 10^{15}$  molecules  $\text{cm}^{-2}$  with an average value of  $4.211 \times 10^{15}$  molecules  $\text{cm}^{-2}$ .

Bhonde *et al* [14] measured  $\text{NO}_2$  during May, June 1988 and February 1989 from zenith sky observations in visible region from the ground at Pune ( $18^\circ 32' \text{ N}$ ,  $73^\circ 51' \text{ E}$ ) and found that  $\text{NO}_2$  vary from  $6.0 \times 10^{15}$  molecules  $\text{cm}^{-2}$  to  $13.0 \times 10^{15}$  molecules  $\text{cm}^{-2}$  while Lal *et al* [15] measured  $\text{NO}_2$  during December 1989 and January 1990 using ground based visible absorption spectrometry at Ahmadabad ( $23^\circ \text{ N}$ ,  $72^\circ \text{ E}$ ) and found that  $\text{NO}_2$  vary from  $0.5 \times 10^{15}$  molecules  $\text{cm}^{-2}$  to  $2.8 \times 10^{15}$  molecules  $\text{cm}^{-2}$ .

It can be seen that the summer months values of  $\text{NO}_2$  reported by Bhonde *et al* [14] are higher and winter month values of  $\text{NO}_2$  reported by Lal *et al* [15] are lower than the corresponding values of  $\text{NO}_2$  presented in this paper. The minimum integrated column observed during winter period and maximum during summer period are in agreement with the reported measurements. But, it should be remembered that the values of Bhonde *et al* and Lal *et al* represent stratospheric  $\text{NO}_2$  column.

*N<sub>2</sub>O :*

The N<sub>2</sub>O absorption feature at 8.560  $\mu\text{m}$  present in the solar spectra recorded during May, June and July 1992 and absorption features at 8.486  $\mu\text{m}$  recorded during November, December 1992 and January 1993, were used to determine N<sub>2</sub>O column abundance.

The N<sub>2</sub>O integrated column for the months of May, June and July 1992 (summer) vary from,  $4.878 \times 10^{18}$  molecules  $\text{cm}^{-2}$  to  $5.620 \times 10^{18}$  molecules  $\text{cm}^{-2}$  with an average value of  $5.228 \times 10^{18}$  molecules  $\text{cm}^{-2}$  and for the months of November, December 1992 and January 1993 (winter) vary from  $4.653 \times 10^{18}$  molecules  $\text{cm}^{-2}$  to  $5.579 \times 10^{18}$  molecules  $\text{cm}^{-2}$  with an average value of  $5.21 \times 10^{18}$  molecules  $\text{cm}^{-2}$ .

*NO :*

The well-isolated nitric oxide line at 5.770  $\mu\text{m}$  present in the solar spectra recorded during May, June and July 1992 and line at 5.415  $\mu\text{m}$  recorded during November, December 1992 and January 1993 were used to determine NO column abundance. The NO column density for the months of May, June and July 1992 (summer) vary from  $3.831 \times 10^{15}$  molecules  $\text{cm}^{-2}$  to  $6.141 \times 10^{15}$  molecules  $\text{cm}^{-2}$  with an average value of  $4.980 \times 10^{15}$  molecules  $\text{cm}^{-2}$  and for the months of November, December 1992 and January 1993 (winter) vary from  $1.143 \times 10^{15}$  molecules  $\text{cm}^{-2}$  to  $5.263 \times 10^{15}$  molecules  $\text{cm}^{-2}$  with an average value of  $2.819 \times 10^{15}$  molecules  $\text{cm}^{-2}$ .

*H<sub>2</sub>O :*

The H<sub>2</sub>O absorption feature at 6.500  $\mu\text{m}$  is used for the determination of integrated column of H<sub>2</sub>O during the months of May, June, July, November, December 1992 and January 1993

The H<sub>2</sub>O integrated columns for the months of May, June and July 1992 (summer) vary from  $0.927 \times 10^{23}$  molecules  $\text{cm}^{-2}$  to  $1.971 \times 10^{23}$  molecules  $\text{cm}^{-2}$  with an average value of  $1.408 \times 10^{23}$  molecules  $\text{cm}^{-2}$  and for the months of November, December 1992 and January 1993 (winter) vary from  $0.585 \times 10^{23}$  molecules  $\text{cm}^{-2}$  to  $1.189 \times 10^{23}$  molecules  $\text{cm}^{-2}$  with an average value of  $0.764 \times 10^{23}$  molecules  $\text{cm}^{-2}$ .

The line parameters, the line strength and the Lorentz half-width for determination of NO<sub>2</sub>, N<sub>2</sub>O, NO and H<sub>2</sub>O are taken from the HITRAN Molecular Database [13]. The time profiles of NO<sub>2</sub>, N<sub>2</sub>O, NO and H<sub>2</sub>O for May, June and July 1992 and November, December 1992 and January 1993 are presented in Figure 4. The ozone Dobson data obtained from IMD for the same period and site is also plotted in this figure.

It is evident from the above results that NO<sub>2</sub> shows seasonal variation with higher values in summer than in winter. The average value of integrated column in summer is larger by a factor of 1.248 as compared to integrated columns in winter months. The average value of column density of N<sub>2</sub>O in summer and in winter months are almost equal

and having only a slight seasonal dependence. The behaviour of integrated column of NO is similar to that of NO<sub>2</sub>. The average value of integrated column of NO in summer months is larger by a factor of 1.766 as compared to integrated column in winter months.

Figure 4. Integrated column of NO<sub>2</sub>, N<sub>2</sub>O, NO, H<sub>2</sub>O and O<sub>3</sub> in May, June, July, November, December 1992 and January 1993.

## 5. Conclusion

We have measured atmospheric emissions in the infrared region from the ground. From these measurements, integrated columns of NO<sub>2</sub>, N<sub>2</sub>O and NO have been determined.

Seasonal fluctuations in the integrated columns of NO<sub>2</sub> and NO have been observed. The summer months are characterised by rather high values of integrated columns of NO<sub>2</sub> and NO with average values  $5.255 \times 10^{15}$  molecules cm<sup>-2</sup> and  $4.980 \times 10^{15}$  molecules cm<sup>-2</sup>, respectively. In winter, the average values of integrated column of NO<sub>2</sub> and NO drop to  $4.211 \times 10^{15}$  molecules cm<sup>-2</sup> and  $2.819 \times 10^{15}$  molecules cm<sup>-2</sup>, respectively. The average values of integrated columns of N<sub>2</sub>O in summer and winter months are almost equal.

Ozone distribution is found to be most sensitive to variation in integrated columns of  $\text{NO}_2$ ,  $\text{NO}$  and  $\text{N}_2\text{O}$  and less sensitive to the variations in the integrated column of water vapour.
